DUPLICATE ALSO

A comparison between the forms of Penman potential evaporation input used in the Meteorological Office Soil Moisture Bulletin (1976) and in MORECS(X).

B G Wales-Smith & J K Mackenzie

Summary

Simple comparisons are made between the use of long-period monthly average p.e. for the half-year October to March and p.e. based on the departure of monthly average daily duration of bright sunshine from long period average for the half-year April to September, on the one hand and monthly p.e. calculated by Penman's formula on the other. The implications of systematic under-estimation of potential evaporation in terms of actual and potential soil moisture deficit are examined.

FH13

3 8078 0001 3123 7

1. Calculation of Penman p.e. and of approximations thereto.

Monthly Penman p.e. totals were calculated for 5 stations (Finningley, Elmdon, Plymouth, Squires Gate and Shoeburyness for the years 1971-1975 using the formula as given by Penman (1948) with the minor modification introduced, in the Meteorological Office, by Grindley (1970); these totals are given in Table 1. Approximations to the above were obtained using monthly average values from October to March and values based on sunshine duration only, from April to October following Smith (1967); these totals are given in Table 2. Similar monthly p.e. calculations for Kew and Eskdalemuir observatories for the period 1964-70 are set out in Table 3. Locations and heights above mean sea level of the 7 stations are given in Fig.1. The Penman formula (see above) is used in MORECS(X) (the Meteorological Office Rainfall and Evaporation Calculation System - Experimental Version); height-adjusted, county average p.e. for October to March and approximations to Penman p.e. based on the departure of sunshine duration from average from April to September form the p.e. input for the soil moisture deficit maps and catchment tables as published in 1976. (A table of Penman formula p.e. estimates, some 2 months in arrear, is currently published for some 80 stations.) The approximate methods involve the implicit assumption that wind speeds, air temperatures and vapour pressures never depart from station average values for the time of year.

2. Comparisons of approximate and calculated Penman p.e. estimates.

The approximate p.e. values (Table 2) are expressed as % of the Penman formula values (Table 1) in Table 4. The 7-year average values are treated in the same way in Table 3. Due to the occurrence of zeros for the approximate averages for two stations in December only 58 1-station, 5-year percentages could be worked; of these 39 were below 100%, 2 were 100% and 17 were above 100%. 25 station-year average percentages are all below 100% except that for March. 7-year percentages for Kew were below 100% except for September, whereas at Eskdalemuir, one of the very few high-ground stations for which reliable

Penman estimates can be made, summer half-year (7-year) percentages were at or above 100% except in August although below 100%, except for October, in the winter half-year. The results are summarised in Table 5 which shows Kew in good agreement with the other 5 English stations but Eskdalemuir having marked deviations from the general pattern of the low ground stations' results. Monthly errors of approximate p.e. used as an estimate of Penman formula p.e. are plotted in Fig.2. The plotted points are 5-year and 7-year monthly average errors and the points joined by the thick lines are 25-station year average errors.

Interesting features are:-

- (a) Eskdalemuir 7-year average errors are positive except in March.
- (b) The 25 station-year graph has winter and summer "peaks" and spring and autumn "troughs".
- (c) 5-year points for Blackpool and Shoeburyness (both coastal stations) are close together in 11 out of 12 months.
- (d) The Kew 7-year points have a broadly similar pattern to the 25 station-year graph.
- (e) The Plymouth 5-year points are all above the 25 station-year graph (large-ve errors).

Implications of using approx.p.e. in lieu of Penman formula p.e.

The 5-station, 5-year (1971-75) averages of p.e. by the approximate and Penman formula methods are compared with 5-station, 1916-50 monthly average rainfalls in Fig.3. Approximate values of month-end potential soil moisture deficit (smd) and of actual soil moisture deficit for 3 inch root constant following Penman (1949) and Grindley (1969) are shown in Fig.4. It can be seen that there would have been, on average, an under-estimation of potential and actual smd for the 5 stations, over the period 1971-75, if the approximation to Penman p.e. had been used in lieu of Penman formula p.e.
